# Introduction

In recent years, the focus in diverse subfields of psychology has been shifting towards complexity, dynamics and within-person perspective (Hamaker, 2012). Among other things, this shift has been facilitated by the growing availability of smartphones and wearables. These devices allow researchers to use the Experience sampling method (ESM) to collect intensive longitudinal data with a high level of ecological validity (Myin-Germeys et al., 2018). Intensive longitudinal data consist of several repeated measurements per day, nested within individual participants (Larson & Csikszentmihalyi, 2014). The use of intensive longitudinal data considerably broadens the extent of research questions psychological researchers can investigate and statistical analyses they can conduct. Importantly, the multilevel structure of intensive longitudinal data allows scientists to investigate both within-person dynamic processes and the individual differences therein between persons (Wright & Zimmermann, 2019). One of the new research avenues that emerged with the growing popularity of intensive longitudinal data is the study of affect dynamics (for an overview, see Houben et al., 2015). The dynamic affect measures make use of the structure of intensive longitudinal data to take the fluctuating nature of affect/emotions into account.

There are two main approaches to capture affect dynamics: fitting models to the data (such as the first-order multilevel autoregressive (MLAR) model, Koval et al. 2021), and computing within-person descriptive statistics (for instance, aurocorrelation). Both the multilevel AR(1) model and the within-person autocorrelation estimates target emotional inertia: the degree to which affective states linger (Kuppens & Verduyn, 2017).

Although some degree of inertia is to be expected in human emotional experiences, a high level of emotional inertia (i. e., a high temporal persistence of emotional states) has been linked to psychological maladjustment (Kuppens et al., 2010). A negative emotion process with a high inertia can get caught in a self-reinforced feedback loop (also called *critical slowing down*, Leemput 2014). This causes the process to be partially resistant to both external influences and inner processes, including emotional regulation (Koval et al., 2015).

The evidence about the association between emotional inertia and the well-being/psychopathology spectrum has grown steadily over the last two decades. A recent meta-analysis indicated an association between emotional inertia (of both positive and negative emotions) and psychological well-being/psychopathology (Houben et al., 2015). More specifically, higher emotional inertia has been linked to lower well-being and higher ocurrence of depressive symptoms (Brose et al., 2015), bipolar disorder (Mneimne et al., 2018), and lower response of depression and anxiety symptoms to cognitive-behavioral therapy (Bosley et al., 2019). However, more recent evidence suggests that the association of inertia (of both positive and negative affect) and psychopathology/well-being is only limited when the mean affect intensities are taken into account Koval et al. (2013).

Despite the popularity of the MLAR(1) models in psychological research, there are several questions about their statistical properties that remain unanswered. One of them is the effect of missing observations

on estimation performance of the MLAR models. This is a pressing issue, given that the presence of missing data in intensive longitudinal datasets is more of a rule than an exception: the average compliance in ESM studies is around 79% (SD = 13.64%; Wrzus & Nebauer 2022), and compliance is associated with study and participant characteristics Eisele et al. (2021).

While Ji et al. (2018) show that the presence of data missing completely at random (MCAR), missing at random (MAR) and not missing at random (MNAR) leads to a considerable bias in point estimates of cross-lagged and autoregressive parameters in multilevel vector autoregressive models when list-wise deletion is used, no similar evidence is available about the MLAR(1) model.

While the MCAR pattern assumes that the participants miss responding to beeps randomly, and each beep has the same probability of being missed, regardless on any other factors (e.g., whether the previous beep was missed, or the intensity of the emotion measured by ESM), many different missing data scenarios can arise in ESM research. For instance, participants could be more likely to miss a series of beeps when they attend a social event. This will result in a block of consecutive missing datapoints, where neither the starting point nor the endpoint of the missing block depend on the intensity of the emotion. Alternatively, probability of an observation being missing can depend on the value of the emotion process itself. For example, a participant can miss responding to an ESM measure of a positive mood because they are not feeling well enough or be less likely to answer an ESM beep in situations that make them feel very good (e.g., they might skip responding an ESM beep when celebrating).

As such, the goal of the present thesis is to investigate whether compliance (i. e., the inverse of the proportion of missing data within each participant of an ESM study) and the different patterns of missingness described in the previous paragraph (MCAR; missing in a block; extreme observations missing) have an effect on estimation bias, variability, and statistical power of the multilevel AR(1) model. Furthermore, the number of participants, number of time points per participant, the simulated fixed AR effect and the variance of the random slopes/AR effects will be manipulated. In the following part, I will describe the multilevel autoregressive model and its assumptions into more details, and summarize the already available evidence about its statistical properties from simulation studies.

# Multilevel AR(1) model

In this subchapter, I will describe the mathematical basis and assumptions of the first-order multilevel autoregressive model with random intercepts and random autoregressive effects, which will be the focus of the simulation part of the thesis. The notation used by Lafit et al. (2020) will be adhered to throughout the thesis.

The MLAR model consists of two levels: the within-person Level 1 and the between-person Level 2. At Level 1, described by Equation (1) (Lafit et al., 2020), each participant's first-order autoregressive process is modelled: The person-specific autoregressive parameter (inertia)  $\gamma_{1i}$  quantifies to what degree the process value  $esm_{it}$  of participant i at time t depends on the lagged process value  $esm_{i,t-1}$ . The person-specific intercept  $\gamma_{0i}$  represents the expected process value  $esm_{it}$  when the lagged variable  $esm_{i,t-1}$  equals 0 (Jongerling et al., 2015). Following the recommendations by Hamaker & Grasman (2015), the predictor (lagged variable) in the simulation will be person-mean centered. The innovation  $\epsilon_{it}$  (i.e., residuals, the part of the process variance that is not explained by the lagged variable  $esm_{i,t-1}$ ) is assumed to be independent and coming from a normal distribution with mean of 0 and variance  $\sigma_e^2$  (Lafit et al., 2020). The model used in the present thesis assumes the innovation variance to be identical for all participants.

$$esm_{it} = \gamma_{0i} + \gamma_{1i} * esm_{i,t-1} + \epsilon_{it} \tag{1}$$

In the multilevel AR(1) model, the person-specific autoregressive effects  $\gamma_{1i}$  and the person-specific intercepts  $\gamma_{0i}$  are allowed to vary between participants. The Level 2 of the MLAR(1) model describes this between-person variability. The Level 2 is defined in Equation (2). Each person-specific autoregressive effect  $\gamma_{1i}$  is a sum of a fixed effect  $\beta_{10}$  and a person-specific random effect  $\nu_{1i}$ . The random effects  $\nu_{1i}$  themselves come from a normal distribution with mean of 0 and variance  $\sigma_{\nu_1}^2$  (Lafit et al., 2020). The same holds for the person-specific intercepts  $\gamma_{0i}$ : they are a sum of a fixed effect  $\beta_{00}$  and a random effect  $\nu_{0i}$  that comes from  $N(0, \sigma_{\nu_0}^2)$ .

$$\gamma_{0i} = \beta_{00} + \nu_{0i} 
\gamma_{1i} = \beta_{10} + \nu_{1i}$$
(2)

#### Assumptions of the MLAR(1) model

In this part, the assumptions of the MLAR(1) model and the way they were taken into account in the present simulation study will be explained.

Stationarity. The MLAR(1) model is used to model stable processes in which no temporal trends (i. e., changes in the process mean over time) are present. As such, it assumes weak stationarity: the (person-specific) process mean, innovation variance, and autoregressive parameter are assumed to not change through the time series (Rovine & Walls, 2006). For this reason, the person-specific autoregressive

effects  $\gamma_{1i}$  are assumed to be bounded by -1 and 1, as autoregressive effects larger than 1 (or lower than -1) cause a change in the process mean (Krone et al., 2016).

Equally spaced measurements. The time-periods that elapsed between each pair of consecutive measurement occasions are assumed to be equal in the following simulation study. In real-life ESM data, the lagged value of the last ESM observation of each day is usually set as missing to account for the fact that the gap between the last night ESM beep and the first morning beep is much larger than the time-gap between the other ESM observations.

#### Estimation procedures

#### TODO

The presence of missing values in an intensive longitudinal dataset decreases the number of observations per participant (or, more specifically, the number of observation-pairs that can be used for the estimation of the model). As such, it can be expected that lower compliance (i. e., lower proportion of ESM beeps that the given participant answered) will make estimation bias more severe.

#### Evidence from simulation studies

Jongerling et al. (2015) investigated the effect of modelling innovation variance as fixed (identical for all participants) instead of random. They found that modelling innovation as fixed when it differs across participants leads to a considerable bias in the estimation of the fixed AR effect. There is an upward bias (overestimation) present when the correlation between the individual AR effects and individual innovation variances is positive, and vice versa. Additionally, Jongerling et al. point out that using the person-means to center the lagged predictor variable leads to a downward bias in the estimation of the fixed AR effect. The effect of person-mean centering the predictor on the estimation performance of the MLAR model was further studied by Hamaker & Grasman (2015). Their simulation study confirmed that person-mean centering leads to an underestimation of the fixed autoregressive effect, especially when the number of time points per participant (T.obs) is low. Still, they recommend using person-mean centering when one is interested in the effect of a between-person predictor on inertia.

In their simulation study comparing the maximum likelihood and Bayesian approaches to estimating the MLAR model, Krone et al. (2016) show that the two estimation procedures have a very similar performance. Furthermore, a higher T.obs leads to more precise estimates, while the effect of N on the estimation performance is small. They also show that a higher variance of the random AR effects leads to a worse estimation precision and that the estimation bias gets smaller when the real fixed AR effect increases. Liu (2017) assessed how violating the normality of the random AR effect distribution influences the estimation performance of the MLAR model. The different distributions of the random AR effects were found to only have a small effect on the estimation performance.

While the simulation studies mentioned above provide an extensive body of evidence about the

statistical properties of the MLAR model under different conditions, several questions remain unanswered. One of them is the effect of missing observations on estimation performance. The presence of missing values in an intensive longitudinal dataset decreases the number of observations per participant (or, more specifically, the number of observation-pairs that can be used for the estimation of the model). As such, it can be expected that lower compliance (i. e., lower proportion of ESM beeps that the given participant answered) will make estimation bias more severe. Additionally, different patterns of missingness might have different consequences on the estimation performance. Ji et al. (2018) show that the presence of data missing completely at random (MCAR), missing at random (MAR) and not missing at random (MNAR) leads to a considerable bias in point estimated of cross-lagged and autoregressive parameters in vector autoregressive models when list-wise deletion is used. However, no similar evidence is available about the MLAR(1) model.

#### Methods

The goal of the present exploratory simulation study is to assess the effects of four different patterns of missing data (data missing completely random, data missing in blocks, and two patterns of data missing dependent on process value; see 1) on estimation performance and bias, standard error, and statistical power for the estimation of the fixed autoregressive effect in the MLAR(1) model. No apriori hypotheses were tested. Apart from the missingness patterns and compliance, we manipulated the number of participants, the number of timepoints per participant, the simulated fixed autoregressive effect, and the variance of random AR effects. The values of the manipulated variables for both studies are reported in Table 1.

#### Simulation procedure

The study followed the general principles of the Monte Carlo simulation procedure described by Lane & Hennes (2018).

Simulation conditions. Two simulation studies, Simulation A and Simulation B, were carried out to investigate the research questions. In Simulation A, no random autoregressive effects were simulated and estimated (i.e., each subject's time-series in the simulation had the same simulated autoregressive effect, and only fixed autoregressive effects were estimated). In Simulation B, random autoregressive effects were simulated and estimated (with the random effects variance set to either 0.05 or 0.1). Both random and fixed intercepts were estimated in Simulations A and B. The multilevel autoregressive model estimated in Simulation A is defined in Equation (3), while Equation (4) describes the model estimated in Simulation B.

$$esm_{it} = \gamma_{0i} + \gamma_{1i} * esm_{i,t-1} + \epsilon_{it}$$

$$\gamma_{0i} = \beta_{00} + \nu_{0i}$$

$$\gamma_{1i} = \beta_{10}$$
(3)

Table 1: Values of the manipulated parameters used in the two simulation studies

Manipulated parameter	Simulation A	Simulation B
Missingness pattern	MCAR, block, extreme-onesided, extreme-twosided	MCAR, block, extreme-onesided, extreme-twosided
Simulated fixed AR effect	0.3,  0.5,  0.7	0.3,  0.7
Variance of random AR effects	-	0.05,  0.1
Compliance	0.4,0.6,0.8,1	0.4,0.6,0.8,1
Number of participants (N)	20, 50	20,  50
Timepoints per participant (T.obs)	20, 50, 100	50, 100

Table 2: Parameters used for the two simulation studies.

Simulation parameter	Simulation A	Simulation B
Fixed intercept	0	0
Variance of random intercepts	3	3
Innovation variance	3	3
Correlation between random	0	0
intercepts and random slopes		
Significance threshold	0.05	0.05
Simulation replicates per cell	1000	1000

$$esm_{it} = \gamma_{0i} + \gamma_{1i} * esm_{i,t-1} + \epsilon_{it}$$

$$\gamma_{0i} = \beta_{00} + \nu_{0i}$$

$$\gamma_{1i} = \beta_{10} + \nu_{1i}$$
(4)

Simulation A followed a  $4 \times 2 \times 3 \times 4 \times 3$  factorial design (yielding 288 simulation conditions in total), and Simulation B followed a  $4 \times 2 \times 2 \times 4 \times 2 \times 2$  design (256 conditions in total). 1,000 replicates per cell (simulation conditions) were simulated. As such, 544,000 datasets were generated (and the same number of models was estimated) in this simulation study. The manipulated variables are listed in Table 1, and the parameters that remained fixed throughout all simulation conditions are reported in Table 2.

Data generation. First, for each of the simulation conditions (i.e., combination of the parameters listed below), 1,000 synthetic datasets were generated. Each dataset contained observations from N simulated participants. A temporally dependent time-series of length T.obs was generated as nested within each simulated participant via a recursive equation. Additionally, for each time-series, a burn-in period with 1,000 observation was generated and later discarded. The within-person error (innovation) vector  $\epsilon_i$  was generated from a  $N(0, \sigma)$  distribution with  $\sigma$  set to 3 in all simulations. The fixed intercept  $\beta_{00}$  was set to 0 across all conditions. The random intercepts  $\nu_{0i}$  for each simulated time-series were sampled from a N(0, 3) distribution in both studies. In Simulation A, only fixed autoregressive effects  $\beta_{10}$  were simulated and manipulated, while both fixed and random autoregressive effects  $\nu_1 i$  were included in Simulation B. No

night gaps were assumed in the simulations. For an overview of the values of all manipulated simulation parameters, please refer to Table 1.

Each time-series was then generated using Equation (1). The initial value was generated as a sum of the person-specific intercept  $\gamma_{0i}$  and the innovation  $\epsilon_{ij}$ , and the following observations were calculated by multiplying the value of the time-series at t-1 by the person-specific autoregressive effect  $\gamma_{1i}$  and adding the person-specific intercept  $\gamma_{0i}$  and the innovation  $\epsilon_{ij}$ . Subsequently, after removing the burn-in datapoints, the first-order lagged version of the time-series was generated, setting the first lagged value as missing.

The non-manipulated simulation parameters  $(\beta_{00}, \sigma_{\nu 0}, \sigma, \rho_{\nu})$  were set following a simulation design from Hamaker & Grasman (2015).

Introduction of missing values. Secondly, missing data were introduced to each of the generated datasets according to the missing data pattern and compliance of the given simulation condition. Four different missingness patterns (corresponding to the hypothetical ESM study scenarios described in the Introduction) were introduced to the data: a) data missing completely at random (MCAR); b) data missing in blocks of consecutive observations; c) lowest (100%-compliance) observations set as missing, and d) highest and lowest (100%-compliance)/2 observations set as missing (for an illustration of the different missing data patterns, see Figure 1).

It can be expected that the different missingness patterns will differ in their effects on the simulation outcomes (estimation bias, standard error, power). This is because with identical proportion of missing data, datasets with different missingness patterns will have different proportions of effective observation-pairs (i.e., proportion of timepoints for which both the observation at t and the observation at t-1 are not missing) used to estimate the autoregressive effect. Figure 1 illustrates the four different missingness patterns on the same ESM time-series.

Fitting a multilevel autoregressive model. After missing values were introduced to the data, a MLAR(1) model was fitted to each of the simulated datasets using the lme function from the nlme R package (Pinheiro et al., 2022) with the value of the time-series at t as the outcome, the lagged (t-1) value of the time-series as the predictor, and the participant number as the grouping variable. We then extracted relevant parameters from the models that converged successfully. Missing values were treated by list-wise deletion. The restricted maximum log-likelihood method with the Broyden-Fletcher-Goldfarb-Shanno optimization algorithm was used to estimate the model.

The predictor (lagged) variable was person-mean centered (i. e., each individual participant's observed mean of the ESM process was subtracted from the value of the lagged variable at each timepoint). Although person-mean centering results in an underestimation of the autoregressive effect (Hamaker & Grasman, 2015), it allows for a clearer interpretation of the within-person effects in multilevel models (Enders & Tofighi, 2007; Hamaker & Muthén, 2020). As a supplementary analysis, we also conducted the simulations without person-mean centering the predictor.

Simulation outcomes. Estimation bias (MSE), the standard error of the estimation, and the

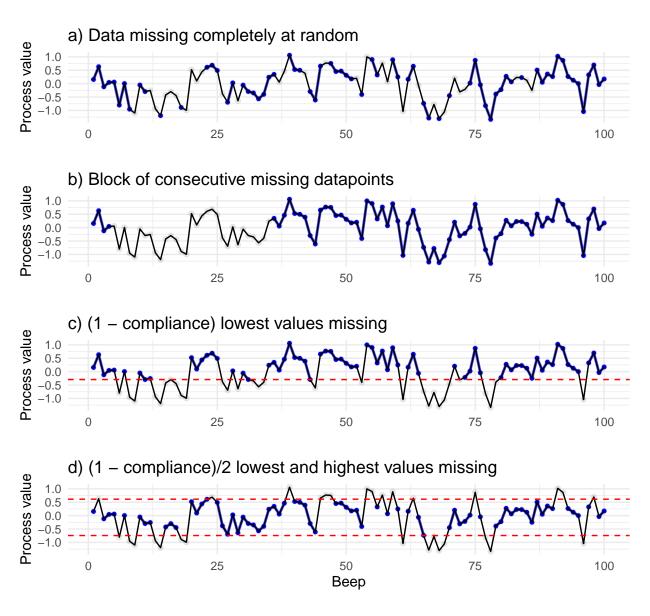

Figure 1: Illustration of the four different missingness pattern used in the simulation study. The blue dots represent observed datapoints, while the light gray dots represent missing values. Compliance is 0.7 in all four patterns.

statistical power to estimate the fixed autoregressive effect  $\beta_{10}$  were the focal outcomes of the study. Additionally, we examined the effect of the manipulated variables on the proportion of models that successfully converged and the bias in the estimation of the person-mean used for centering of the predictor (lagged) variable.

Estimation bias was computed as the difference between the real (simulated) fixed autoregressive effect  $\beta_{10}$  and the estimated fixed autoregressive effect  $\hat{\beta}_{10}$  in each simulation replicate. As such, the dataset with estimation bias contained 1,000 rows per simulation condition.

Standard error (SE) and statistical power were calculated for each simulation condition (i.e., 1 row per condition). Statistical power was calculated as the proportion of simulation replicates (within the given simulation condition) in which the p-value for the estimated fixed autoregressive effect  $\hat{\beta}_{10}$  was below the significance threshold ( $\alpha = 0.05$ ) and the number of simulation replicates that converged successfully.

The bias in the estimation of the person-mean of the time-series was computed as the average difference between the real process mean  $\mu_i$  (5) and the observed person-mean  $\hat{\mu_i}$  (computed after the missing data were introduced).

$$\mu_i = \frac{\beta_{00} + \nu_{0i}}{1 - (\beta_{10} + \nu_{1i})} \tag{5}$$

#### Reproducibility and code/data availability

The simulations were conducted in R version 4.2.1 (R Core Team, 2021). The study was conducted with emphasis on reproducibility of the results (Pawel et al., 2022). As such, we provide all data (simulation results) used for the reported analyses, as well as the full reproducible R code for the simulations (including the custom functions created for the purposes of the study), and the code used to generate the plots and result tables (available at https://github.com/benjsimsa/AR-missing-simulations) The repository also includes a sessionInfo document that lists the versions of the packages used for the study. The present thesis was written using R Markdown (Allaire et al., 2022).

Additionally, the *renv* R package (Ushey, 2022) was used to set up a reproducible R environment and improve reproducibility by creating a project-local package library. For reproducible file referencing, the R package *here* (Müller, 2020) was used. For more information about the custom functions, simulation code, and the structure of the GitHub repository itself, please refer to the file README.md in the repository.

## Results

#### Simulation A

The descriptive results for all 288 conditions included in Simulation A are reported in Table 16 (see Appendix).

#### Outcome: Estimation bias (MSE)

ANOVA. We used a  $4 \times 2 \times 3 \times 4 \times 3$  factorial Type I ANOVA (with estimation bias as an outcome and number of participants, number of time points per participant, missingness type, compliance, and the simulated fixed autoregressive effect, as well as their two-ways interactions, as predictors) to assess which of the manipulated factors had a considerable influence on estimation bias. The results from every simulation run (i. e., 1,000 results per condition = 288,000 rows) were combined into a single dataset for the analysis. Given the very large sample size (which would make even negligible differences significant) and the exploratory character of the analysis, p-values and significance thresholds were not used make inferences. Instead, we used a threshold of 0.14 for the partial  $\omega^2$ , indicating a large effect size (Field et al., 2012). This cutoff will be used for all ANOVA results throughout the Results section. The partial  $\omega^2$  was chosen as the less biased alternative to partial  $\eta^2$  (Okada, 2013). The results and effect sizes are reported in Table 3.

Four main effects above the effect size threshold of 0.14 were found: the main effect of missingness type ( $\omega^2 = 0.73$ ), compliance ( $\omega_p^2 = 0.63$ ), the number of time points per participant ( $\omega_p^2 = 0.26$ ), and the simulated fixed slope ( $\omega_p^2 = 0.14$ ). Furthermore, the interaction between the missingness type and compliance ( $\omega_p^2 = 0.54$ ) had an effect size above the cut-off.

The main effects of missingness type and compliance are visualised in Figure 2 and Figure 3 (respectively), while the interaction between missingness type and compliance is depicted in Figure 4.

Figure 2 shows that while the underestimation of the fixed slopes is fairly low (although still considerable) when the observations are missing completely at random or in block, it becomes severe when only the most extreme values (both at one side and at both sides) are missing. Additionally, the underestimation of the fixed slopes becomes more severe as the compliance gets lower.

The average estimation bias when compliance is 0.8 (i.e., roughly the average compliance of ESM studies in psychology) is -0.13. As a consequence, many estimates of emotional inertia in psychological research could be seriously downward biased. Furthermore, the estimates are slightly biased even when compliance is 1 (i. e., there are no missing data; average bias: -0.04). This is in line with the findings about estimation bias caused by person-mean centering in multilevel autoregressive models (Hamaker & Grasman, 2015).

Zooming in on the interaction between compliance and missingness type (Figure 4) suggests that the effect of compliance on estimation bias is dramatically more severe for the two conditions in which the most extreme values of the process were set as missing (as compared to the other two conditions, i. e., data

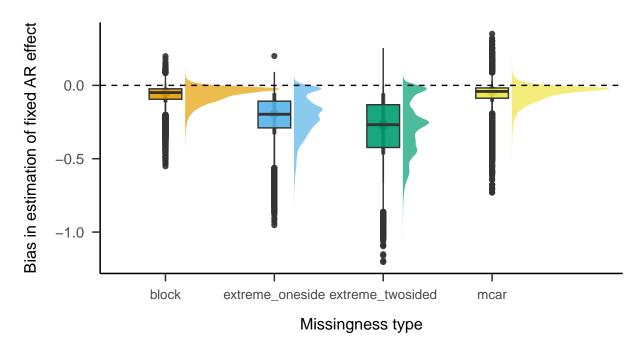

Figure 2: The effect of compliance on the bias in estimation of the fixed slopes.

MCAR and missing in blocks). In the worst-case scenario (low compliance of 0.4; the most extreme values at both sides missing), the average estimation bias was -0.48. Given that the average simulated fixed slope was 0.5, these results imply that even rather large autocorrelations can be estimated as close to 0 in studies in which the compliance is low and the missingness pattern is non-random. At the same time, the results concerning data MCAR and missing in blocks are encouraging. Even in a low-compliance (0.4) condition, the average estimation bias was -0.08 for the former and -0.09 for the latter.

The average estimation bias for all combinations of missingness type and compliance (averaged over the different values of the number of participants, time points per participant and simulated fixed slope) is reported in Table 4.

#### Outcome: Standard error

**Descriptive statistics.** The average standard errors for the different combinations of number of participants, time points per participant and compliance are reported in Table 5.

ANOVA. To examine the effect of the manipulated parameters on the standard error of the estimation of the fixed slopes, we combined the results for each condition (1,000 simulation runs) into a single row. As such, the dataset used for the following analyses had 288 rows in total. A a  $4 \times 2 \times 3 \times 4 \times 3$  factorial Type I ANOVA was used to analyse the data. The full ANOVA results and effect sizes are reported in Table 6.

The main effects of the number of participants ( $\omega_p^2 = 0.68$ ), number of time points per participant ( $\omega_p^2 = 0.68$ ) and compliance ( $\omega_p^2 = 0.66$ ) crossed the cut-off for effect size.

Additionally, the interaction between the number of time points per participant and compliance ( $\omega_p^2 = 0.28$ ), number of participants and time points per participants ( $\omega_p^2 = 0.07$ ), and between the number of participants and compliance ( $\omega_p^2 = 0.22$ ) was found.

Figure 5 depicts the interaction between the number of time points per participant and compliance, while Figure 6 shows the interaction between the number of participants and compliance.

#### Outcome: Statistical power

**Descriptive statistics.** The statistical power for each combination of the manipulated parameters is reported in Table (BIG TABLE TODO). As an illustration, the effects of compliance, missingness type, the number of participants and the number of time points per participant when the simulated fixed slope is 0.3 are visualised in Figure 7. Consistent with the results about estimation bias, statistical power is the lowest in the two conditions with the most extreme datapoints missing. For the conditions with data missing completely at random and data missing in consecutive blocks, power is very high even when the compliance is low for most conditions (except for the two conditions with T = 20).

A peculiar pattern is worth pointing out in the plot: in the two conditions with T=20 and the most extreme data missing at both sides (green dashed line), the statistical power is higher when compliance is 0.4 compared to when compliance is 0.6. This counterintuitive result is likely due to the fact that the underestimation is the most severe when the most extreme values at both sides are missing. As such, some of the estimates of the fixed slope will be negative, and their magnitude will be large enough for them to reach statistical significance.

**ANOVA.** A  $4 \times 2 \times 3 \times 4 \times 3$  factorial Type I ANOVA was used to analyse the effect of the

manipulated parameters (288 conditions in total) on statistical power. The results are reported in Table 7.

Four main effect above the cut-off for the effect size were found: the effect of compliance ( $\omega_p^2=0.43$ ), of missingness type ( $\omega_p^2=0.36$ ), simulated fixed slope ( $\omega_p^2=0.18$ ), and the effect of the number of time points per participant ( $\omega_p^2=0.17$ ).

#### Simulation B

In Simulation B, random AR effects were included both in the data generating procedure and in the estimated models. The variance of random AR effects  $(\sigma_{\nu 1}^2)$  was manipulated as an additional simulation factor (2 values: 0.05 and 0.1). For an overview of all manipulated and fixed simulation parameters, please refer to Table 1. The descriptive results for all 256 simulation conditions are reported in Table 17 in the Appendix.

#### Outcome: Estimation bias

To evaluate the effect of the number of participants, number of time points per participant, missingness type, compliance, the variance of random AR effects, and the simulated fixed autoregressive effect on the bias in the estimation of the fixed AR effect in Simulation B, a  $4\times2\times2\times4\times2\times2$  factorial Type I ANOVA was used. The results from every simulation run (256 conditions \* 1000 runs per condition) were combined into a single dataset. An identical inference criterion ( $\omega_p^2 \geq 0.14$ ) as in the analysis of Simulation A was used. The ANOVA results are listed in Table 8.

Interestingly, compared to the results from Simulation A (see Table 3), the effect of T.obs on estimation bias ( $\omega^2 = 0.03$ ) is much smaller and does not reach the effect size threshold. The three main effects that do reach the cut-off in Simulation B are the effect of missingness type ( $\omega_p^2 = 0.65$ ), compliance ( $\omega_p^2 = 0.48$ ), and the real fixed AR effect ( $\omega_p^2 = 0.46$ ). The only interaction that reached the cut-off was the interaction between missingness type and compliance ( $\omega_p^2 = 0.45$ ). The interaction is visualised in Figure 8. The pattern of the interaction is very similar to the pattern of the interaction between missingness type and compliance in Simulation A (see Figure 4). Interestingly, when compared to the results of Simulation A, the average estimation bias is slightly worse for the MCAR and block missingness types and slightly less severe for the two conditions with the extreme values missing (compare Table 9 and Table 4). However, the overall conclusion remains the same as in Simulation A: there is a considerable downward estimation bias that becomes more severe the lower the compliance rate is, and it is most severe for the condition in which the most extreme data at both sides are missing.

#### Outcome: Standard error

**ANOVA.** The results of the  $4 \times 2 \times 2 \times 4 \times 2 \times 2$  factorial ANOVA used to assess the influence of the manipulated factor on the standard error are reported in Table 11. Compared to Simulation A, more main effects of the manipulated factors crossed the effect-size cut-off: the effect of number of participants  $(\omega_p^2 = 0.93)$ , compliance  $(\omega_p^2 = 0.53)$ , number of time points per participant  $(\omega_p^2 = 0.33)$ , and the value of the simulated fixed AR effect  $(\omega_p^2 = 0.28)$ . Additionally, the interaction between compliance and the number of time points per participant  $(\omega_p^2 = 0.18)$  crossed the threshold.

Figure 9 illustrates the main effect of N (as the most important factor) on standard error, while Figure 10 shows the interaction between compliance and T.obs. While the results are comparable to

Simulation A, the SE is slightly higher for the same N/T.obs combinations in Simulation B.

#### Outcome: Statistical power

Descriptive statistics. The statistical power for each combination of the manipulated parameters in Simulation B is reported in Table (BIG TABLE TODO SIM2). The effects of compliance, missingness type, the number of participants and the number of time points per participant when the simulated fixed slope is 0.3 are shown in Figure 11. For the sake of clarity, only the results for simulation conditions in which the  $\sigma_{\nu 1}^2 = 0.1$  are visualised.

**ANOVA.** A  $4 \times 2 \times 2 \times 4 \times 2 \times 2$  factorial Type I ANOVA was used to analyse the effect of the manipulated parameters on statistical power. The results are reported in Table 12.

Missignness type ( $\omega_p^2 = 0.4$ ) together with compliance ( $\omega_p^2 = 0.38$ ) were the two main effects with the largest influence on the statistical power to detect the fixed AR effect. The value of the simulated AR effect

has a large effect ( $\omega_p^2=0.3$ ) as well. Three interactions crossed the effect size threshold: missingness type\*compliance ( $\omega_p^2=0.41$ ), missingness type\*simulated fixed AR ( $\omega_p^2=0.23$ ), and compliance\*simulated fixed AR ( $\omega_p^2=0.23$ ).

#### Supplementary analysis: No person-mean centering

To investigate whether the results presented above hold when the predictor (i.e., the lagged variable) is not person-mean centered, we conducted a supplementary analysis. All parameters were identical to Simulation A, except for the fact that the predictor was not person-mean centered. We found that both the standard error and the bias in the estimation of the fixed autoregressive effect is considerably smaller when the predictor is not person-mean centered.

**Estimation bias.** In an ANOVA with the bias in the estimation of the fixed autoregressive effect as the outcome (Table 13), only the effect of the number of beeps per participant, missingness type, and the interaction between missingness type and compliance exceeded the effect size cut-off.

In contrast to the results of Simulation A, the effect of the manipulated factors on estimation bias is much smaller. Moreover, Figure 12 shows that while there is still slight underestimation when the most extreme values are missing, the magnitude of the underestimation is much smaller than in Simulation A. Additionally, when the observations are missing completely at random or in blocks, a slight overestimation of the fixed autoregressive effect occurs. The estimation becomes very precise as compliance gets higher (Figure 13).

Standard error. The results from ANOVA with Standard error of estimation (when estimating the

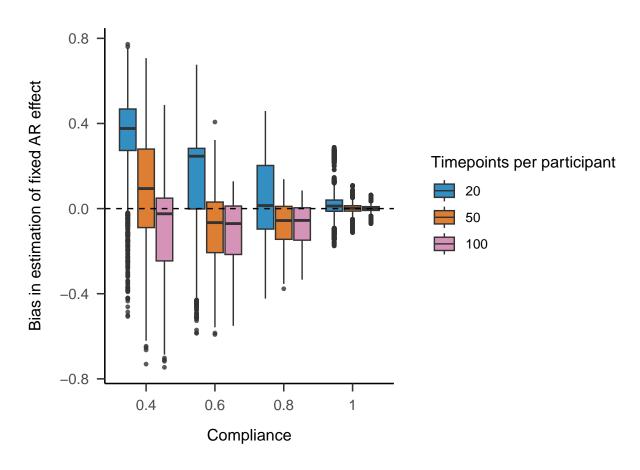

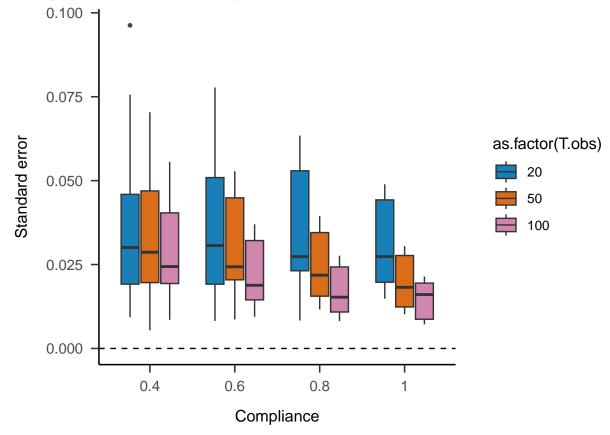

Figure 13: Supplementary analysis (no person-mean centering): The effect of the interaction between compliance and number of timepoints on estimation bias.

fixed autoregressive effect) are reported in Table 14. The main effects of the number of timepoints per participants and missingness type, as well as the interaction between compliance and the number of timepoints, crossed the effect size cut-off ( $\omega_p^2 > 0.14$ ).

The standard errors in the estimation of fixed AR effect are considerably smaller when person-mean centering is used (Table 15) compared to Simulation A (Table 5). Figure ?? illustrates the interaction between compliance and the number of timepoints.

Taken together, these results suggest that the results of MLAR(1) models obtained without person-mean centering the predictor are more robust to the presence of missing value with regards to estimation bias and standard error (i.e., the estimation bias and standard error are much lower when the predictor is not person-mean centered). Still, both the magnitude and the direction of the bias depend on the type of missingness.

### Discussion

We conducted two Monte Carlo simulation studies to address a gap in knowledge about the influence of missing data on the estimation performance of the multilevel autoregressive model. In Simulation A, we only estimated and simulated fixed autoregressive effects (together with both fixed and random intercepts), while in Simulation B, both fixed and random autoregressive effects were simulated and estimated. Three outcomes were evaluated in both simulations: the estimation bias, standard error of the simulations, and statistical power. Four values of compliance and four missingness patterns (data MCAR, data missing in a block of consecutive observations, the highest values missing, and the highest and lowest values missing) were varied across the simulations. The other manipulated factors included the number of participants, the number of time points per participant, the simulated value of the fixed AR effect, and the variance of the random AR effects.

The two parameters related to missing data (compliance and missingness pattern) emerged as very important factors influencing all three outcomes. In both simulations, missingness type and compliance (and the interaction between the two) were the factors with the largest effect on the bias in the estimation of the fixed AR effect. Similarly, both missingness type and compliance had a strong influence on the statistical power to detect the fixed AR effect in both simulations. With regards to the standard error of the simulation results, compliance was found to have a very large effect (more so in Simulation A than in Simulation B), while the effect of missingness type was only moderate.

Our results corroborate the conclusions about the importance of the number of time points per participant for precise estimation of the autoregressive effects (Hamaker & Grasman, 2015; Krone et al., 2016). In general, the estimation bias became considerably less severe as the ESM time-series length per participant increased. *T.obs* also had a large effect on statistical power. However, our simulations show that the context of missingness matters: when the compliance is low and the data are missing MCAR or in blocks, the underestimation of the fixed AR effect caused by the missing data (and the negative consequences for statistical power) becomes less severe very quickly as *T.obs* increases. On the other hand, when the missingness is dependent on the value of the process itself (i. e., the most extreme observations are missing), increasing compliance appears to be more important for estimation precision and statistical power than the length of the time-series. In other words, it can be said that the presence of missing data exacerbates Nickell's bias (Nickell, 1981) - an estimation bias introduced by person-mean centering in multilevel models.

While Krone et al. (2016) found that estimation bias becomes smaller as the simulated fixed AR effect becomes larger, we found an opposite pattern: estimation bias was larger as the simulated fixed AR effect became larger.

Overall, there was always some degree of estimation bias present in the simulations, ranging from very severe (when T.obs and compliance were low, and the missingness of data was dependent on the process value) to mild (when compliance was high and the data were missing either MCAR or in block). This bias

in estimation might be one of the driving forces behind the low value added by estimates of emotional inertia to the prediction of psychopathology and well-being, pointed out by Dejonckheere et al. (2019). Additionally, while the simulation studies did not explicitly assess the bias in the estimation of individual autoregressive effects, the results suggest that some individual differences in inertia estimates might not be caused by real differences in inertia, but due to the bias caused by missingness: for two individual participants with an identical real autoregressive parameter but different compliance and missingness patterns, the inertia estimates can vary considerably.

Our results have several implications for the design choices in psychological research using the multilevel autoregressive model to estimate emotional inertia. First, in line with previous simulation studies, we recommend for researchers to focus on increasing T.obs rather than N in order to increase the statistical power and the precision of the inertia estimates. In other words, for optimal statistical performance, it is more effective to make the data collection period longer (or schedule more beeps per day) than to collect data from more participants. Secondly, while the time-series length is important, researchers should aim to design their ESM studies in a way that will make compliance as high as possible. According to recent evidence about compliance in ESM studies, these design choices include providing financial incentives to participants (Wrzus & Neubauer, 2022) and including less items in ESM questionnaires (Eisele et al., 2020). Furthermore, the results suggest that the potential presence of missing data should be accounted for in power analyses for ESM studies. In an ideal case, a researcher should have an idea about what the average compliance in their study could be and what missingness patterns might be present in the data. Of course, this is not entirely feasible, as it might be difficult to estimate the average compliance, and real-life ESM data will likely include a mixture of different missing data patterns, both at the within- and between-person level. Still, to avoid overestimating statistical power for planned studies, it is advisable to include several different missing data scenarios in the power simulations as a sensitivity check.

#### Directions for future research

The present thesis provides evidence about estimation bias being made more severe by lower compliance and by patterns of missingness that depend on the process value itself. Nonetheless, the insight into the mechanisms driving this bias remains limited. Several plausible explanations of the bias arise. First, the estimation bias was the most severe when the most extreme observations at both ends of the ESM process distribution were missing. This finding can be linked to the evidence about tails (i. e., the extreme ends) of distributions containing the most information about the scale of the distribution (Zheng & Gastwirth, 2002). However, further investigation is needed to provide more understanding about whether the tails also provide crucial information about the autoregressive effect.

Secondly, the different bias values for different missingness patterns could be partly caused by the fact that the number of "effective" observation-pairs (i. e., pairs of current and lagged values where both values are not missing) used to estimate the autoregressive parameters differs between the missignness patterns.

For example, the number of effective observation-pairs will be larger when the data are MCAR than when they are missing in a block. However, the results of the present thesis seem to contradict this explanation. On the one hand, estimation bias was found to be very similar when data are MCAR and missing in blocks (although the two missingness patterns come with a very different number of observation-pairs). On the other hand, the estimation bias was much larger for the conditions with the most extreme values set as missing, compared to the condition with data MCAR (even though the number of effective observation-pairs is generally higher for the "extreme" conditions than when data are MCAR). As such, this explanation of estimation bias appears to be less plausible than the explanation described in the previous paragraph.

#### Limitations

First, while the two simulation studies include a wide range of scenarios and parameter combinations, our results are far from comprehensive, and they largely depend on the simulation parameters. However, the reproducible code available from the GitHub repository

(https://github.com/benjsimsa/AR-missing-simulations) provides a sufficient framework for an interested reader to rerun the analyses with different parameters and modify the code to better fit the peculiarities of their specific study sample and research questions.

Furthermore, the results depend on several assumptions, which were problematised as being too simplistic in previous research. We assumed that the innovation variance  $\sigma$  was identical for all the participants, and that the random intercepts (and random slopes in Simulation B) came from a normal distribution. Additionally, we only focused on normally distributed affective processes. While a normal distribution can be assumed for ESM measures of positive emotions, negative affective processes are usually heavily right-skewed in the general population (Haslbeck et al., 2022). Additionally, we assumed that the analysed ESM time-series are measured without any error; however, recent evidence shows that this is very often not the case in real-world research (Dejonckheere et al., 2022; Schuurman & Hamaker, 2019), and unreliability can lead to further attenuation of the estimated parameters (Wenzel & Brose, 2022). While person-mean centering was carried out using observed means in the simulations we conducted, different ways of person-mean centering, such as using latent person-means, might be more appropriate (Gistelinck et al., 2021). Another assumption of the present simulations that is unlikely to hold in real-world data is the homogeneity of compliances and missing data patterns within each simulated dataset. In the real world, it can be expected for different missingness patterns to be present in the data at both the between- and within-person level.

Finally, although we took steps to make the simulations reproducible by making all code and results publicly available, using R packages *here* and *renv*, and reporting the sessionInfo for every simulation, a large number of packages with many dependencies were used, which might be detrimental to reproducibility in the long term.
